1 **Abstract**

2 The temporal trends of fungicides in surface and ground water in ninety samples,
3 including both surface waters (12) and ground waters (78) from an extensive vineyard area
4 located in La Rioja (Spain) were examined between September 2010 and September 2011.
5 Fungicides are used in increasing amounts on vines in many countries, and they may reach the
6 water resources. However, few data have been published on fungicides in waters, with
7 herbicides being the more frequently monitored compounds. The presence, distribution and
8 year-long evolution of seventeen fungicides widely used in the region and a degradation
9 product were evaluated in waters during four sampling campaigns. All the fungicides
10 included in the study were detected at one or more of the points sampled during the four
11 campaigns. Metalaxyl, its metabolite CGA-92370, penconazole and tebuconazole were the
12 fungicides detected in the greatest number of samples, although myclobutanil, CGA-92370
13 and triadimenol were detected at the highest concentrations. The highest levels of individual
14 fungicides were found in Rioja Alavesa, with concentrations of up to 25.52 $\mu\text{g L}^{-1}$, and more
15 than 40% of the samples recorded a total concentration of $>0.5 \mu\text{g L}^{-1}$. More than six
16 fungicides were positively identified in a third of the ground and surface waters in all the
17 sampling campaigns. There were no significant differences between the results obtained in the
18 four sampling campaigns, and corroborated a pattern of diffuse contamination from the use of
19 fungicides. The results confirm that natural waters in the study area are extremely vulnerable
20 to contamination by fungicides, and highlight the need to implement strategies to prevent and
21 control water contamination by these compounds.

24 evaluation; vineyards.

25

26 **1. Introduction**

27 In agriculture, the more intensive use of pesticides to prevent and combat fungi, weeds and
28 insects, the greater the potential discharge of these compounds into aquatic ecosystems. These
29 products or their degradation products, may remain in the environment, and this has become a
30 growing concern in recent years (Picó and Barceló, 2015; Ccanccapa et al., 2016; Teklu et al.,
31 2016). Intensive agriculture combined with factors enhancing leaching and the
32 hydrogeological characteristics of the unsaturated zone may lead to increased levels of
33 pesticides in groundwater (Vryzas et al., 2012). As a result of this, a persistent threat to the
34 environment and even to human health may occur, and it has required the drafting of strict
35 directives by the European Commission (EC) to minimize the negative effects on the
36 environment. Council Directive 98/83/EC (EC, 1998) set the limits for pesticides in water
37 intended for human consumption at $0.1 \mu\text{g L}^{-1}$ for individual pesticides and $0.5 \mu\text{g L}^{-1}$ for the
38 sum of all pesticides. More recently, EC Directive (EC, 2000, 2008) established a framework
39 for Community action in the field of water policy, and approved a list of 33 priority
40 compounds in the field of water policy. One-third of the compounds included on this list are
41 pesticides, reflecting the EC's concern at the presence of these compounds in water (EC,
42 2013).

43 Fungicides are a group of pesticides used to combat fungi and (or) their spores. They
44 can be chemical or biological, and act systemically or via contact with plant surfaces to
45 prevent foliar diseases in a wide range of crops. The main market for fungicide is in Europe,
46 where these compounds are critical components for the protection of grapevine and other
47 crops (Oliver and Hewitt, 2014). According to data of FAOSTAT (2015) the use of fungicides
48 and bactericides in the European Union was approximately 143500 t of active ingredients in
49 2013, which was higher than that in North America countries (85000 t of active ingredients).

50 A number of studies have reported fungicides in European waters. For example
51 fungicides of the azole family have been found in samples from Swiss Midland lakes (Kahle
52 et al., 2008); the metabolites of some fungicides (tolylfluanid, chlorothalonil, and
53 trifloxystrobin) were found in waters from different areas in Germany (Reemtsma et al.,
54 2013), and several fungicides were also detected by Gonçalves et al. (2007) in the waters of a
55 vulnerable zone in Portugal, while carbendazim was the fungicide most frequently detected in
56 several rivers and groundwaters influenced by agriculture in Serbia (Dujakovic et al., 2010).

57 Elsewhere azoxystrobin was the most frequently detected fungicide, followed by by
58 metalaxyl, propiconazole, myclobutanil, and tebuconazole in southern and central USA
59 (Battaglin et al. 2011). Also in the US, Reilly et al. (2012) detected at least one fungicide in
60 75% and 58% of the surface and ground waters, respectively, from three geographical areas of
61 intense fungicide use. In Vietnam, isoprothiolane is the one most frequently detected in
62 samples from locations influenced by rice growing (Van Toan et al., 2013), in Costa Rica it
63 has been found in waters from an area impacted by nearby pineapple and banana plantations
64 (Echeverria-Saenz et al., 2012), and in Australia it was shown the presence of residues of
65 many different organic fungicides in the surface waters of a horticultural production
66 catchment (Wightwick et al. 2012).

67 In Spain, the occurrence of a relatively low number of fungicides waters in different
68 areas around the Mar Menor lagoon (SE Spain) (Moreno-González et al., 2013), in Andalusia
69 (southern Spain) (Belmonte Vega et al., 2005) and in the Ebro River basin (Ccanccapa et al.,
70 2016) have been found. Fungicides were also detected in soils from the La Rioja (northern,
71 Spain), mainly metalaxyl and its metabolite, kresoxim-methyl and triadimenol (Pose-Juan et
72 al., 2015). Metalaxyl, cyprodinil and penconazole were detected in the sediments and soils in
73 different parts of Spain, such as a small river basin partially occupied by vineyards in Galicia
74 (Bermúdez-Couso et al., 2007). Tebuconazole was detected in the basin of the River

75 Llobregat (Catalonia, Spain), although pesticide residues do not seem to pose a high risk to
76 the local biota (Masiá et al., 2015). However, to date, there is clearly a lack of data regarding
77 the presence and temporal evolution of fungicides in natural waters, especially in areas where
78 they are widely used, such as agricultural zones where the main crop is vine.

79 Spain is the European country with the most land set aside for vineyards (14% of the
80 total area), and is the third in terms of wine production, behind Italy and France (International
81 Organisation of Vine and Wine - OIV, 2015). La Rioja is the fifth region in Spain in grape
82 production. Its wines are protected by the oldest Qualified Designation of Origin (DOCa) in
83 Spain. The DOCa Rioja is the Spanish market leader for fine wines, with nearly 40% of the
84 total sales (Rioja DOCa - Qualified Designation of Origin, 2015). Hildebrandt et al. (2008)
85 and Navarro et al. (2010) reported the presence of different pesticides (including fungicides)
86 along the River Ebro, with some sampling points in La Rioja itself, although the monitoring
87 was too sporadic to provide a clear picture of water conditions in this area. Previous studies
88 we have carried out in this area have revealed the presence of a wide range of fungicides in
89 surface and ground waters (Herrero-Hernández et al., 2012 and 2013). However, no study of
90 the temporal variation of fungicides in surface and ground waters has been conducted,
91 although one is required, considering the seasonal application of these compounds in
92 vineyards and to other crops in this area.

93 The aim of this work was to study the intra-annual trends of fungicides widely used in
94 vine cultivation in ground and surface waters from the wine-growing region of La Rioja
95 (Spain), and evaluate the pollution of natural waters by these compounds according to the
96 levels permitted by EU legislation ($0.1 \mu\text{g L}^{-1}$) (EC, 1998). Ninety sampling points, including
97 wells, springs, uptakes and rivers, were sampled in the vineyard region of DOCa Rioja, and
98 17 fungicides were monitored in samples collected in four campaigns over the course of a
99 year in order to explore the following: i) The temporal trends of the individual concentrations

100 of fungicides in waters, ii) the temporal trends of the total concentrations of fungicides in
101 waters, and iii) the variability of the fungicide concentrations in all the samples from different
102 subareas and sampling campaigns.

103

104 **2. Materials and methods**

105 *2.1. Chemicals*

106 The standards of 17 fungicides and a degradation product were supplied by Fluka, Dr.
107 Ehrenstorfer (Augsburg, Germany), Syngenta (Basel, Switzerland), and Riedel-de Haën
108 (Seelze-Hannover, Germany) (minimum purity higher than 98%). The common names and
109 physicochemical properties of the fungicides are listed in Table S1 in the Supplementary
110 Material.

111

112 *2.2. Characterization of the study area*

113 The DOCa Rioja wine region is located in northern Spain, straddling the River Ebro
114 (Fig. 1). The valley has a maximum width of around 40 km and an area of ~ 64,000 ha. It is
115 covered by vineyards with the DOCa designation that occupy successive terraces to an
116 altitude of around 700 m above sea level, and produce 280-300 million litres of wine per year.
117 This area is divided into three subareas: Rioja Alta (ALT), with an Atlantic climate and
118 chalky-clay, ferrous-clay or alluvial soils; Rioja Alavesa (ALV), with an Atlantic climate, and
119 chalky-clay soils on terraces and small plots, and Rioja Baja (BJ), with a drier and warmer
120 climate and alluvial and ferrous-clay soils (Herrero-Hernández et al., 2013). The region
121 usually records mild temperatures between 7°C and 20°C and an annual rainfall between 300
122 and 400 mm (Rioja DOCa - Qualified Designation of Origin, 2015) with a rainfall pattern
123 mainly winter dominated. The mobility of pesticides is favoured in the area because the soils

124 generally have a low organic matter (OM) content (<1.5 %) and a sandy clay loam or sandy
125 loam texture (Pose-Juan et al., 2015).

126

127 *2.3. Sample collection and analytical methodology*

128 A total of ninety water samples were collected from three different agricultural areas
129 in the three different subareas of Rioja Alavesa (15 points), Rioja Alta (34 points), and Rioja
130 Baja (41 points). Twelve samples were surface waters (two on the River Ebro at the end of La
131 Rioja region, six on the main tributaries, one on the Lodosa canal, and three on small rivers),
132 and seventy-eight samples were groundwaters from private wells (44) with depths <10 m (39)
133 or >10 m (5), and uptakes or springs (Herrero-Hernández et al., 2013). Table S2 in the
134 Supplementary Material provides the characteristics of the sampling points in terms of water
135 type (surface or ground water) and water depth (well, spring, uptake or river), crop cultivated
136 and watering use. The wells were located inside the cultivated fields or next to them, and they
137 were generally used for irrigation purposes. Samples were collected manually or after 10 min
138 of water pumping, using the pipes and the electrical pumps used by the farmer in each case.
139 They were collected over a year in four sampling campaigns: September 2010 (Sept-10),
140 March 2011 (Mar-11), June 2011 (Jun-11) and September 2011 (Sept-11).

141 All the water samples were collected in 2 L brown glass bottles and transported to the
142 laboratory in iceboxes. They were filtered through nitrocellulose screens with Minisart NY 25
143 filter 0.45 µm (Sartorius Stedim Biotech, Germany), and fungicides were removed by solid-
144 phase extraction after a SPE preconcentration step with polymeric cartridges (Oasis HLB, 60
145 mg, Waters). Samples analysis was carried out by gas chromatography–mass spectrometry
146 (GC–MS) or by liquid-chromatography-mass spectrometry (LC–MS), as indicated in Herrero-
147 Hernandez et al. (2012 and 2013). The analytical conditions and quality control parameters
148 are shown in Tables S3 and S4, respectively, in the Supplementary Material.

149

150 *2.4. Statistical analysis and data processing*

151 Pearson correlations were calculated to relate the concentrations of fungicides in
152 waters and the properties of fungicides. Principal component analysis (PCA) was used as a
153 tool to explore the data variability of the fungicide concentrations in all the samples from
154 different subareas and sampling times. This multivariate data analysis transforms the set of
155 possible correlated measured variables into a reduced set of a few uncorrelated variables, and
156 it is used to facilitate the assessment of the potential contamination sources from data
157 obtained in large-scale monitoring studies. A total of 6480 results were evaluated from the
158 analysis of 360 samples. The matrix of scores and the matrix of loadings were obtained to
159 give information, respectively, on the distribution of patterns or sources of contamination
160 among samples (map of samples) and on the contribution of the original variables to each one
161 of these contamination patterns or sources (map of variables). IBM SPSS Statistics 22
162 software was used for data processing.

163

164

165 **3. Results and discussion**

166 *3.1. Intra-annual evolution of the individual concentrations of fungicides in waters in DOCa* 167 *Rioja*

168 Residual concentrations of fungicides were detected in most of the samples analysed
169 in the three subareas of DOCa Rioja (Tables 1-4), although there were several points where
170 fungicides were detected in any of the sampling periods. All the fungicides were detected in
171 one or more of the four sampling campaigns, and most of them were detected in one or more
172 of the samples; only iprovalicarb and cyproconazole were not detected in any sample in
173 September 2010 and March 2011, respectively. Other compounds were detected in five or

174 fewer samples, such as nuarimol, trifloxystrobin and dimethomorph in March 2011, nuarimol
175 and trifloxystrobin in June 2011, and iprovalicarb, azoxystrobin and dimethomorph in
176 September 2011 (See Tables 1-4). These results confirm how vulnerable the natural waters in
177 the study area are to contamination by fungicides due to their widespread use in vineyards -
178 the main crop. There was, nonetheless, a high percentage of sampling points that met the EU
179 quality standard for individual compounds, with concentration levels below $0.1 \mu\text{g L}^{-1}$
180 according to the percentages of total samples in which the fungicides were not detected, or
181 were detected below or above this legally established limit (See Fig. 2)

182 The most abundant and ubiquitous compounds detected in the first sampling campaign
183 (Sept-10) were metalaxyl (52 samples, 12 of them with concentrations $> 0.1 \mu\text{g L}^{-1}$ (52/12)
184 and a maximum concentration (C_{max}) of $1.299 \mu\text{g L}^{-1}$), its metabolite CGA-92370 (51/8, and
185 C_{max} of $16.47 \mu\text{g L}^{-1}$), penconazole (43/13 and C_{max} of $0.342 \mu\text{g L}^{-1}$), tebuconazole (42/14
186 and C_{max} of $1.968 \mu\text{g L}^{-1}$) and kresoxim-methyl (40/16 and C_{max} of $0.287 \mu\text{g L}^{-1}$). Other
187 compounds detected in this sampling in high concentrations were myclobutanil, azoxystrobin
188 and triadimenol, at C_{max} of 12.61, 4.778 and $4.332 \mu\text{g L}^{-1}$ respectively. In all cases, these
189 C_{max} were detected in samples from Rioja Alavesa.

190 Some of these compounds, such as tebuconazole (67/3 and C_{max} of $3.236 \mu\text{g L}^{-1}$),
191 metalaxyl (45/12 and C_{max} of $8.015 \mu\text{g L}^{-1}$), kresoxim-methyl (45/7 and C_{max} of $0.574 \mu\text{g}$
192 L^{-1}), and penconazole (41/5 and C_{max} of $3.683 \mu\text{g L}^{-1}$), were also the most ubiquitous
193 compounds in the sampling campaign carried out in Mar-11, together with pyrimethanil (58/6
194 and C_{max} of $0.234 \mu\text{g L}^{-1}$) and triadimenol (40/12 and C_{max} of $3.103 \mu\text{g L}^{-1}$). The metabolite
195 of metalaxyl and myclobutanil were the other compounds detected in high concentrations
196 (C_{max} of 7.226 and $7.208 \mu\text{g L}^{-1}$, respectively). C_{max} data were recorded for tebuconazole,
197 myclobutanil, triadimenol, metalaxyl and its metabolite in Rioja Alavesa, for penconazole,
198 triadimenol and metalaxyl in Rioja Alta, and for metalaxyl and triadimenol in Rioja Baja.

199 The same fungicides were also detected in the sampling campaigns carried out in Jun-
200 11 (metalaxyl (59/19 and Cmax of 18.85 $\mu\text{g L}^{-1}$), its metabolite CGA-92370 (55/9 and Cmax
201 of 1.643 $\mu\text{g L}^{-1}$), and triadimenol (34/14 and Cmax of 8.470 $\mu\text{g L}^{-1}$), together with
202 azoxystrobin (50/3 and Cmax of 0.463 $\mu\text{g L}^{-1}$) and myclobutanil (33/18 and Cmax of 3.091
203 $\mu\text{g L}^{-1}$); and in the last sampling campaign carried out in Sept-11, penconazole (47/12 and
204 Cmax of 0.476 $\mu\text{g L}^{-1}$), metalaxyl (39/8 and Cmax of 1.848 $\mu\text{g L}^{-1}$), cyproconazole (39/4 and
205 Cmax of 0.154 $\mu\text{g L}^{-1}$), tebuconazole (37/7 and Cmax of 3.023 $\mu\text{g L}^{-1}$) and myclobutanil (33/6
206 and Cmax of 5.068 $\mu\text{g L}^{-1}$). High concentrations were also detected in Rioja Alavesa and in
207 Rioja Alta in the June-11 and Sep-11 sampling campaigns (Tables 1-4).

208 It is evident that metalaxyl, its metabolite CGA-92370, penconazole and tebuconazole
209 were the fungicides detected in a greater number of samples, although myclobutanil, CGA-
210 92370 and triadimenol were detected in higher concentrations. Fig. 3 shows the evolution of
211 the sum of concentrations of these compounds in all the samples over the four campaigns in
212 the three subareas of DOCa Rioja. Peak concentrations were found in March (penconazole
213 and tebuconazole), June (metalaxyl and myclobutanil), and September (CGA-92370,
214 myclobutanil, triadimenol and tebuconazole), and they could be related to the application of
215 these fungicides following the recommendations made by the authorities and experts for
216 tackling *ad hoc* diseases in the different areas (Gobierno de La Rioja, 2016). The highest
217 fungicide concentrations were obtained for samples located in Rioja Alavesa, except for
218 penconazole, which recorded a concentration peak in Rioja Alta.

219 A certain relationship was found between water solubility, GUS index or Kow, and the
220 total concentrations of these fungicides, although it was significant only for water solubility
221 (excluding metalaxyl) in the June sampling ($r=0.88$, $p<0.10$), for the GUS index in the
222 September sampling ($r=0.82$, $p<0.10$), and for Kow ($r=-0.94$ and -0.99 ($p<0.01$)) in the March

223 and June samplings, respectively. However, no significant correlations were found for these
224 parameters when all the fungicides were considered jointly.

225 Residues of the fungicides included in this study were also detected in surface waters
226 in the province of Almería (SE Spain) (pyrimethanil, myclobutanil, benalaxyl, nuarimol,
227 tebuconazole and azoxystrobin) (Ruiz Gil et al., 2008). Furthermore, the levels of fungicides
228 found are similar to those reported in other European agricultural regions in Germany
229 (Berenzen et al., 2005) and Greece, where triadimenol, cyproconazole, pyrimethanil and
230 benalaxyl were detected in several water samples (Thomatou et al., 2013), and more recently,
231 fungicides have been detected in 14% of the samples in the basin of Lake Vistonis, with
232 metalaxyl being the compound found in higher concentrations (Papadakis et al., 2015).

233 Other studies found residues of some of the fungicides included in this work in several
234 agricultural regions in countries as Argentina (tebuconazole with a mean concentration of
235 $0.033 \mu\text{g L}^{-1}$) (De Geronimo et al., 2014), Costa Rica (myclobutanil, triadimenol, cyprodinil
236 and metalaxyl reaching values of $0.082 \mu\text{g L}^{-1}$ for metalaxyl) (Echeverría-Sáenz et al., 2012),
237 Brazil (tebuconazole, azoxystrobin and trifloxystrobin reaching concentrations up to $0.037 \mu\text{g}$
238 L^{-1} in river water samples) (Montagner et al., 2014), USA in samples from streams, ponds,
239 and shallow groundwaters in areas of intense fungicide use (azoxystrobin, pyrimethanil,
240 cyprodinil and dimethomorph with concentrations up to $0.180 \mu\text{g L}^{-1}$ (Reilly et al., 2012) and
241 in water samples from streams in 13 states (azoxystrobin, metalaxyl, myclobutanil,
242 tebuconazole and trifloxystrobin with concentrations up to $1.13 \mu\text{g L}^{-1}$) (Battaglin et al.,
243 2011), and Australis in the surface water samples (myclobutanil, pyrimethanil, cyproconazole,
244 trifloxystrobin, and fenarimol at concentrations $>0.2 \mu\text{g L}^{-1}$) (Wightwick et al. 2012).

245

246 *3.2. Intra-annual evolution of the total concentration of fungicides in waters in DOCa Rioja*

247 The temporal evolution of the total concentration of fungicides was studied to
248 establish the 'good chemical status' of surface and ground waters according to the European
249 Directive (EC, 2008). This Directive establishes a limit of $0.5 \mu\text{g L}^{-1}$ for the aggregate
250 concentration of pesticides to be applied to drinking water. In groundwater (Fig. 4), the results
251 in Sept-10 showed up to 11 samples in Rioja Alta (35%) with Σ concentration of fungicides
252 above $0.5 \mu\text{g L}^{-1}$, and a number of samples in Rioja Alavesa (2) and Rioja Baja (1) with
253 Σ concentrations above $25 \mu\text{g L}^{-1}$. In Mar-11, up to nine samples were detected in Rioja Alta
254 (29%) with Σ concentration of fungicides above $0.5 \mu\text{g L}^{-1}$, as well as samples with
255 concentrations $>15 \mu\text{g L}^{-1}$ in Rioja Alavesa (2), and $>10 \mu\text{g L}^{-1}$ in Rioja Alta (1) and Rioja
256 Baja (1). In Jun-11, up to nine samples were detected in Rioja Alta (29%) containing
257 fungicide concentrations above $0.5 \mu\text{g L}^{-1}$, and samples with concentrations above $8 \mu\text{g L}^{-1}$
258 were found in Rioja Alavesa (3) and Rioja Baja (1). In the last sampling campaign (Sept-11),
259 up to five samples were found in Rioja Baja (17%) containing fungicides adding up to more
260 than $0.5 \mu\text{g L}^{-1}$, and there were three samples in Rioja Alavesa with concentrations above
261 $9 \mu\text{g L}^{-1}$.

262 No significant relationship was found between the depth of the groundwater and the
263 total content of fungicides. The wells deeper than 10 m recorded, in general, the lowest
264 content of fungicides although it was not possible to find relationships with parameters of
265 soils or local hydrologic conditions. However it was observed that less polluted groundwaters
266 corresponded to wells located in areas where the main crops are fruit trees, cereals, etc. with
267 lower amounts of fungicides than in vineyard are applied. On the other hand it worth noting
268 that the high levels of total concentration over the four sampling campaigns in Rioja Alavesa
269 (2), Rioja Alta (1) and Rioja Baja (1) were found at the same sampling points. They
270 correspond to groundwater samples from shallow wells (1-3 m) in areas where the vineyard is

271 the only crop and this may be due to improper handling of these products in the vicinity of
272 wells.

273 In surface waters, the results obtained in the four sampling periods indicated
274 Σ concentrations of fungicides above $0.5 \mu\text{g L}^{-1}$ in 0-2 samples (0-66%) in Rioja Alavesa, in
275 2-3 samples (33-100%) in Rioja Alta, and in 1-2 samples (16-66%) in Rioja Baja.

276 This total concentration of fungicides in waters is generally due to the presence of a
277 different number of compounds. In groundwaters, the results indicate that no fungicides were
278 detected in just seven of the 78 samples in Sept-10, eight in Mar-11, two in Jun-11 and
279 seventeen in Sept-11, but more than six fungicides were detected in a higher number of
280 samples (29 in Sept-10, 23 in Mar-11, 25 in Jun-11, and 23 in Sept-11) (Fig 5a). In surface
281 waters, the number of samples positively identifying more than six fungicides was four in
282 Sept-10, five in Mar-11 and Jun-11, and six in Sept-11 (Fig 5b). The percentage of samples
283 with a high number of fungicides (29-37% of groundwaters and 33-50% of surface waters)
284 again highlights the widespread use of different compounds on local crops (vines and fruits)
285 due to the different diseases affecting them, which are mainly Downy mildew (*Plasmopora*
286 *viticola*), *Botrytis cinerea*, and Powdery mildew (*Uncinula necator*).

287

288 3.3. Principal component analysis

289 Principal component analysis (PCA) was used as a multivariate analysis tool to
290 explore the relationships among the concentrations of fungicides measured in different
291 subareas and sampling campaigns, and evaluate their variability. The results indicate that all
292 the variables are explained to a greater or lesser extent by the factors obtained from the
293 analysis. In agreement with the explained total variance, the number of principal components
294 (PCs) with eigenvalues >1 that better explain the variables were six and five, respectively, for
295 ground and surface waters. These PCs explain 70.93% of the variance of fungicide data from

296 groundwater samples, whereas a higher variance (73.79%) was explained by the data from
297 surface water samples. Similar variances were explained when data were arranged by subarea
298 or sampling campaign.

299 For groundwater, the first PC explained 25.38% of the total data variance, and for
300 surface waters this first PC explained 25.71% of the variance (Table 5). In general, all the
301 loadings were positive and high, indicating a pattern of diffuse contamination from the use of
302 fungicides in the areas studied. This first PC was mainly explained for groundwaters by the
303 presence of myclobutanil, tebuconazole and dimethomorph, and for surface waters by the
304 presence of cyprodinil and pyrimethanil, while other fungicides made a lower contribution to
305 PC1. Certain variables, such as triadimenol, metalaxyl or its metabolite CGA-92370, recorded
306 a greater loading in other PCs (Table 5). The results indicate that CGA-92370 and metalaxyl
307 did not dominate similar PCs, although CGA-92370 is produced by the degradation of
308 metalaxyl.

309 Score plots for PC1 vs. PC2, representing the distribution of sampling sites from
310 different subareas and sampling campaigns corresponding to groundwaters (Fig. 6a) and
311 surface waters (Fig. 6b) as well as the distribution of sampling sites from different campaigns
312 corresponding to ground and surface waters (Fig. 7) were only included. Score plots for data
313 distributed in other limited regions of space encompassed by different well-defined PC axes
314 are not shown because they are not relevant. The distribution of variables in different
315 groundwaters was fairly uniform around the origin of the axis, although some sites in Rioja
316 Alavesa and Rioja Alta are outstanding (Fig. 6a). The variables from Rioja Alavesa
317 groundwaters stand out in all the sampling campaigns, whereas the variables from Rioja Alta
318 groundwaters only do so in the Mar-11 sampling. This agrees with the high values found for
319 metalaxyl, CGA-92370, tebuconazole, triadimenol and myclobutanil in some sites in Rioja
320 Alavesa, and penconazole in some sites in Rioja Alta. The outstanding points in the Mar-11

321 sampling might indicate residual contamination from previous campaigns at certain hot spots.
322 The variables were also uniformly distributed around the origin of the axis, with some sites
323 standing out in different surface waters. In this case, Rioja Alta sites recorded greater
324 variability in the four sampling campaigns, whereas they were only outstanding for Rioja
325 Alavesa in the Jun-11 sampling.

326 The variables are distributed around the origin of the axis in different surface waters,
327 whereas they are distributed in the lower quadrant with only some outstanding points through
328 the upper right quadrant in groundwaters in all the sampling campaigns (Fig. 7). Surface
329 water recorded lower levels of fungicides than groundwaters and a lower detection rate. These
330 results could be explained by the behavior (sorption and leaching) of fungicides in soils which
331 is depending on the characteristics of soils and fungicides. In a previous study a significant
332 correlation was found between residues of some fungicides in soils from Rioja region and soil
333 characteristics (Pose-Juan et al., 2015). This finding was also reported in other studies on the
334 distribution of pesticides in other areas (Hildebrandt et al., 2008), and it was explained by the
335 rapid degradation of pesticides in surface water, whereas a lower degradation of these
336 compounds could occur in groundwater, making this medium more vulnerable, especially
337 when groundwater is used for human consumption.

338

339 **4. Conclusions**

340 The study carried out between September 2010 and September 2011 along the wine
341 growing region of La Rioja showed the great diversity of fungicides in the study area and its
342 occurrence in water samples with a dispersed pattern of fungicide concentrations. All the
343 fungicides included in the study were detected in one or more of the four sampling
344 campaigns, and most of them were detected in one or more of the samples in all the
345 campaigns. Metalaxyl, its metabolite CGA-92370, penconazole and tebuconazole were the

346 most frequently detected fungicides, although myclobutanil, CGA-92370 and triadimenol
347 were detected in higher concentrations. These results are consistent with the widespread use
348 of these compounds which are those more applied following information provided by local
349 farmers. The highest concentrations of fungicides were obtained in samples located in Rioja
350 Alavesa regard other zones of the study area, except penconazole with the highest total
351 concentration located in Rioja Alta. Up to 40%, 35% and 25% of groundwaters with a total
352 concentration of fungicides $>0.5 \mu\text{g L}^{-1}$ were detected in the areas studied, and approximately
353 a quarter of the total waters recorded more than six fungicides in all the sampling campaigns.
354 Furthermore, the concentrations in groundwaters were greater than in surface waters in all
355 cases, and samples not too deep located close to vineyard showed the higher concentrations.
356 This could indicate an easier percolation of fungicides in these cases and highlight the need to
357 implement strategies to enhance the retention of these compounds by soils for effective water
358 protection given the imperative use of these compounds in agriculture. The use of biobeds
359 during the handling of pesticides or the washing of equipment and the application of organic
360 amendments to soils may be some of these strategies.

BJ-S5	Surface water (Iregua river)	-	Vineyards	
BJ-S6	Surface water (Leza river)	-	Vineyards	
BJ-S7	Surface water (Villar de Arnedo river)	-	Vineyards	

Table S3. Conditions for analytical determination and quality control parameters of the SPE-LC-MS method applied to the analysis of fungicides in surface and ground waters.

Fungicide	SIM ion m/z	V cone (V)	SIM window	RT (min)	Recovery ^a (%)	RSD (%)	r ² (0.1-2.0 µg L ⁻¹) ^b	LOD ^c (µg L ⁻¹)	LOQ ^d (µg L ⁻¹)
Cymoxanil	199.2	35	1	8.3	76	13	0.991	0.022	0.069
Cyproconazole	292.2	20	4	18.3	76	13	0.992	0.021	0.059
Azoxystrobin	404.2	25	4	18.3	85	11	0.995	0.017	0.052
Iprovalicarb	321.3	20	5	19.9	86	7	0.995	0.016	0.037
Dimethomorph	388.2	25	5	20.6	82	12	0.995	0.017	0.062
Benalaxyl	326.2	25	6	25.2	89	15	0.992	0.015	0.048
Cyprodinil	226.2	40	6	25.5	73	9	0.994	0.018	0.043
Trifloxystrobin	409.1	20	6	26.9	64	7	0.991	0.016	0.037

^a Calculated from the replicated analysis (n = 5) of spiked (0.1 µg L⁻¹) groundwater samples; ^b Linear calibration range; ^c LOD Detection limit for a signal-to-noise ratio of 3. ^d LOQ Quantification limit for a signal-to-noise ratio of 10

Table S4. Conditions for analytical determination and quality control parameters of the SPE-GC-MS method applied to the analysis of fungicides in surface and ground waters.

Compound	SIM window	RT (min)	Monitored ions (Abundance)	Recovery ^a (%)	RSD ^a (%)	r ² (0.1-1.5 ^b µg L ⁻¹)	LOD ^c (µg L ⁻¹)	LOQ ^d (µg L ⁻¹)
			Target (m/z) Qualifier Ions (m/z)					
CGA 92370	1	7.3	148 120 (572)/91 (322)	78	17			
Pyrimethanil	3	10.0	198 199	65	14	0.992	0.031	0.078
Metalaxyl	4	12.9	45 206 (326)/132 (299)	108	12	0.997	0.001	0.006
Penconazole	5	16.3	248 159 (851)/161 (577)	83	14	0.996	0.002	0.005
Triadimenol	5	16.4	112 128 (906)/168 (745)	77	15	0.993	0.005	0.021
Flutriafol	5	20.6	123 164 (552)/219 (255)	80	17	0.997	0.005	0.013
Myclobutanil	5	21.4	179 82 (451)/150 (449)	83	15	0.999	0.003	0.013
Kresoxim-methyl	5	22.2	116 131 (533)/206 (516)	91	14	0.989	0.016	0.041
Tebuconazole	6	24.6	125 250 (847)/70 (492)	84	17	0.997	0.006	0.022
Nuarimol	6	25.3	107 139 (765)/235 (744)	83	14	0.994	0.124	0.284

^a Calculated from the replicated analysis (n = 5) of spiked (0.1 µg L⁻¹) groundwater samples; ^b Linear calibration range. ^c LOD Detection limit for a signal-to-noise ratio of 3. ^d LOQ Quantification limit for a signal-to-noise ratio of 10
